Progressive brain volume changes in schizophrenia are thought to be due principally to the disease. However, recent animal studies indicate that antipsychotics, the mainstay of treatment for schizophrenia patients, may also contribute to brain tissue volume decrement. Because antipsychotics are prescribed for long periods for schizophrenia patients and have increasingly widespread use in other psychiatric disorders, it is imperative to determine their long-term effects on the human brain.

Objective: To evaluate relative contributions of 4 potential predictors (illness duration, antipsychotic treatment, illness severity, and substance abuse) of brain volume change.

Design: Predictors of brain volume changes were assessed prospectively based on multiple informants.

Setting: Data from the Iowa Longitudinal Study.

Patients: Two hundred eleven patients with schizophrenia who underwent repeated neuroimaging beginning soon after illness onset, yielding a total of 674 high-resolution magnetic resonance scans. On average, each patient had 3 scans (≥2 and as many as 5) over 7.2 years (up to 14 years).

Main Outcome Measure: Brain volumes.

Results: During longitudinal follow-up, antipsychotic treatment reflected national prescribing practices in 1991 through 2009. Longer follow-up correlated with smaller brain tissue volumes and larger cerebrospinal fluid volumes. Greater intensity of antipsychotic treatment was associated with indicators of generalized and specific brain tissue reduction after controlling for effects of the other 3 predictors. More antipsychotic treatment was associated with smaller gray matter volumes. Progressive decrement in white matter volume was most evident among patients who received more antipsychotic treatment. Illness severity had relatively modest correlations with tissue volume reduction, and alcohol/illicit drug misuse had no significant associations when effects of the other variables were adjusted.

Conclusions: Viewed together with data from animal studies, our study suggests that antipsychotics have a subtle but measurable influence on brain tissue loss over time, suggesting the importance of careful risk-benefit review of dosage and duration of treatment as well as their off-label use.
More recent literature reviews have highlighted the potential role of antipsychotics in influencing brain volume deficits in schizophrenia and its implications.22-26

The goal of the current study was to comprehensively evaluate the contributions of 4 potential causative factors that may mediate progressive brain volume decrement in schizophrenia: illness duration, long-term antipsychotic treatment, illness severity, and substance abuse. Extending our previous work,19 the present study has the largest available cohort of schizophrenia patients who have undergone longitudinal MRI assessments. We examined 211 patients and collected 674 high-resolution MRI brain scans (averaging 3 scans per patient; at least 2 and up to 5 per patient) over an extended period (mean, 7 years; up to 14 years). Furthermore, multiple within-patient MRI scans coupled with an extensive clinical database provide for more robust estimates of brain volume trajectories.

Understanding the long-term effects of antipsychotics on the brain has wider clinical ramifications beyond treatment of patients with schizophrenia. Given the sharp rise in antipsychotic utilization,27 especially among pediatric and geriatric populations,27-30 examining the possibility of antipsychotic-associated brain tissue loss has important implications for assessing the risk-benefit ratio in a large number of psychiatric patients.

Study participants were obtained through the Iowa Longitudinal Study (ILS).31 To be eligible, participants must have met DSM-III or DSM-IV criteria for schizophrenia-spectrum disorders and have been presenting for treatment of their first psychotic episode. At intake, patients underwent an extensive evaluation, including standardized clinical rating scales (Scale for Assessment of Negative Symptoms,32 Scale for Assessment of Positive Symptoms,33 Comprehensive Assessment of Symptoms and History,34 and Psychiatric Symptoms You Currently Have [PSYCH]35) and MRI. After intake, patients were examined at 6-month intervals by means of longitudinal follow-up versions of the Comprehensive Assessment of Symptoms and History and PSYCH, which included illness severity measures, alcohol and illicit drug use, and detailed information regarding antipsychotic treatment. Follow-up assessments were completed by experienced research personnel who have undergone interrater and test-retest reliability training.36 At follow-up assessments after 2, 5, and 9 years and every 3 years thereafter, MRI was repeated. Participant retention in the ILS is 63%. Sociodemographic and illness characteristics of patients who remained in the study are comparable to those of patients who dropped out.37

PATIENTS

The 211 patients (152 men and 59 women) in this report were selected from the larger ILS sample on the basis of having (1) a DSM-IV diagnosis of schizophrenia (n=192) or schizoaffective disorder (n=19) (verified at follow-up by psychiatrists’ consensus), and (2) undergone 2 or more MRI brain scans. There were 674 MRI scans (211 patients each had 2 scans, 139 had 3, 82 had 4, and 31 had 5) covering a mean follow-up period of 7.2 years (SD, 3.9 years; range, 1.9-14.0 years), and inter-scan intervals were approximately 3 years. At the initial MRI, mean (SD) age was 26.3 (7.6) years, and most patients had received minimal antipsychotic treatment (as detailed later).

METHODOLOGY

Methods

To be eligible, participants must have met DSM-III or DSM-IV criteria for schizophrenia-spectrum disorders and have been presenting for treatment of their first psychotic episode. At intake, patients underwent an extensive evaluation, including standardized clinical rating scales (Scale for Assessment of Negative Symptoms, Scale for Assessment of Positive Symptoms, Comprehensive Assessment of Symptoms and History, and Psychiatric Symptoms You Currently Have [PSYCH]) and MRI. After intake, patients were examined at 6-month intervals by means of longitudinal follow-up versions of the Comprehensive Assessment of Symptoms and History and PSYCH, which included illness severity measures, alcohol and illicit drug use, and detailed information regarding antipsychotic treatment. Follow-up assessments were completed by experienced research personnel who have undergone interrater and test-retest reliability training. At follow-up assessments after 2, 5, and 9 years and every 3 years thereafter, MRI was repeated. Participant retention in the ILS is 63%. Sociodemographic and illness characteristics of patients who remained in the study are comparable to those of patients who dropped out.

METHODS

MRI ACQUISITION AND ANALYSIS

High-resolution brain anatomic MRI data were collected by means of 1 of 2 imaging protocols on two 1.5-T MR scanners (General Electric Medical Systems, Milwaukee, Wisconsin). The type of imaging protocol was dependent on when the patient first enrolled in the ILS. For patients who entered the study before calendar year 2000, their initial and follow-up MRI scans were collected with the first imaging protocol (termed MR5). In patients who were enrolled in 2000 or later, all MRI scans were obtained with the second imaging protocol (termed MR6; see the supplementary “Methods” section and eTable 1 [http://www.archgenpsychiatry.com] regarding imaging parameters, data processing, and comparability). Of the 674 MRI brain scans, 570 were MR5 scans derived from 168 patients. Patients in the MR5 group had been followed up longer (mean, 8.05 years vs 4.06 years for the 43 patients in the MR6 group). Otherwise, there were no significant differences between the MR5 and MR6 groups on sociodemographics or illness characteristics (t=1.27, P=.21).

In this study, we examined the following regions of interest: total cerebral tissue volume, total GM and white matter (WM), and GM:WM subdivided by Talairach atlas–based cerebral lobes (frontal, temporal, and parietal), lateral ventricles, sulcal cerebrospinal fluid (CSF), caudate, putamen, thalamus, and cerebellum (see the supplementary “Methods” section regarding region of interest measurements and the eFigure showing schematic representation of regions of interest).

ANTIPSYCHOTIC TREATMENT, ILLNESS SEVERITY, AND SUBSTANCE MISUSE

At each 6-month follow-up assessment, detailed information during the preceding 6 months was obtained from all available informants (ie, patient, family members, significant others, and medical records) and summarized in a timeline that records specific antipsychotic dose, treatment duration and medication adherence, illness severity, and alcohol/illicit drug misuse.

Antipsychotic treatment is naturalistic given that the long-term nature of the study precludes a random assignment design. Patients received “treatment as usual” in the community. Antipsychotic choice and dosages were left to the patient and his or her treating psychiatrist. Although it can be difficult to make precise measurements of lifetime antipsychotic exposure by using retrospective methods, our assessments every 6 months combining multiple information sources provide the most accurate treatment data possible in a long-term, large-sample naturalistic study. In this report, we use lifetime antipsychotic treatment up until the time of each MRI scan (expressed as mean daily antipsychotic dose [chlorpromazine (CPZ) milligram equivalents per day]) to assess relationships between antipsychotic treatment and brain volumes. To derive mean daily (total) antipsychotic dose, each antipsychotic was first converted to CPZ milligram equivalent units,39-41 and then all antipsychotic doses were summed and divided by the number of treatment days (see eTable 2 for CPZ equivalencies of individual antipsychotics).

Because intensity of treatment may be closely related to symptom severity and because we wished to examine its potential effect on brain change independently, we also examined the impact of illness severity on brain change. Since there is no single measure that comprehensively captures illness severity in schizophrenia, we explored multiple alternative approaches (eTables 3 and 4): Global Assessment Scale (GAS),42 symptom severity (mean of psychotic, negative, and disorganized symptoms [global ratings on the Scale for Assessment of Negative Symptoms and Scale for Assessment of Positive Symptoms] or as 3 separate symptom domains), global psychosocial functioning (rating scale within...
PSYCH (mean daily clozapine dose, and a composite score derived from the 4 preceding illness severity measures (weighted sum based on principal component analysis eigenvalues). Only results using GAS scores were available for the 4 follow-up periods; lower score means greater illness severity) are presented herein. The GAS score is widely used in clinical studies, provides anchors to enhance interrater reliability, and has good psychometric properties. Mean GAS scores, negative/positive symptom ratings, and global psychosocial functioning scores were highly intercorrelated with one another (Pearson \( r \) = 0.82). Mean daily clozapine dose was less strongly correlated with the other 3 measures of illness severity (Pearson \( r \) = 0.14). Furthermore, regardless of which individual illness severity measure or the weighted sum composite score was used, results (eg, Table 4) were similar to those using mean GAS score. Research personnel assessing GAS scores showed good agreement and reliability on their ratings (intrarater and test-retest intraclass correlation coefficients, 0.79 and 0.62, respectively).

Substance abuse is another potential confounder for the study of change in brain measures. At follow-up assessments every 6 months, severity of alcohol use and severity of illicit drug use were each assessed by a 6-point ordinal scale: 0, no use; 1, occasional use without impairment; 2, occasional heavy use without impairment; 3, occasional use (weekend binges) without social or occupational consequences; 4, daily use with moderate impairment; and 5, daily use with severe impairment leading to inability to function in social or occupational roles. Severity of alcohol/illicit drug misuse was derived by averaging both scores.

Abbreviations: APS, antipsychotic; CPZ, chlorpromazine; MRI, magnetic resonance imaging; NA, not applicable.

*First follow-up is the time interval between the initial and first follow-up images; second follow-up, the time interval between the first and second follow-up images; etc.

*One CPZ dose-year = 100 mg of CPZ per day for 1 year.

Analyses were performed with SAS statistical software (version 9.2; SAS Institute, Inc, Cary, North Carolina). Random regression coefficients were used to evaluate the relationships between MRI brain volume changes and the 4 predictor variables: follow-up duration (time between MRI scan and initial scan), antipsychotic treatment (mean daily antipsychotic dose), illness severity (mean GAS score), and alcohol/illicit drug misuse (mean severity score). For each region of interest, within-patient repeated measures of brain volumes were the dependent variables in each mixed model. Follow-up duration and an intercept term were specified as random effects to model within-patient correlations in brain volumes across time. The 4 predictor variables were entered concurrently as fixed effects, allowing us to examine the influence of one predictor variable on brain volume changes independent of the other 3 predictors. An antipsychotic treatment \( \times \) follow-up duration interaction term was also included in the statistical model to further assess the effects of antipsychotic treatment on within-patient changes in brain volumes over time. Mean daily antipsychotic dose was mildly to moderately correlated with mean GAS score and with follow-up duration (Spearman \( r \) = −0.21 and 0.42, respectively; \( P < .001 \)). Otherwise, there were weak intercorrelations between these predictor variables (Spearman \( r \) ≤ 0.12). Furthermore, there was no evidence that these 4 predictor variables were highly collinear in the mixed models (tolerance values ≥ 0.74). Intracranial volume at initial MRI scan, sex, imaging protocol (MR5 vs MR6), and age at initial MRI scan were included as covariates. A 2-sided \( P < .05 \) was used to determine statistical significance.

### RESULTS

#### ANTIPSYCHOTIC TREATMENT BEFORE AND DURING LONGITUDINAL FOLLOW-UP

The sample had minimal antipsychotic treatment before study enrollment (Table 1); there were 31 antipsychotic-naive patients, and median treatment duration was 0.43 year. The types of antipsychotics patients received reflect prevailing medication prescribing patterns in the United States at the time (initial MRI scan, 1991-2006; last scan, 1995-2009). Typical antipsychotics were the predominant treatment before the initial MRI scan. Nonclozapine atypical antipsychotics became the main choice (in approximately two-thirds of the sample) during subsequent interscan intervals. About 25% of patients received clozapine treatment. Patients received adequate antipsychotic dosages, and treatment adherence was good (mean [SD] of 1.90 [0.82] on a 5-point clinical rating scale in which 1 is excellent; 2, good [ie, patient takes all psychiatric medications as prescribed]; rarely, if ever, forgets or chooses not to take medications]; 3, fair; 4, poor; and 5, nonadherent).

#### INDEPENDENT EFFECTS OF FOLLOW-UP DURATION AND ANTIPSYCHOTIC TREATMENT ON BRAIN VOLUMES

Follow-up duration provides an indication of whether progressive brain changes occur over time. It had significant main effects on all brain volumes (Table 2, \( P = 5.39, P < .02 \) except for total cerebral WM, frontal...
WM, temporal WM, and cerebellum ($F = 2.03, P ≥ .16$). Longer duration of follow-up was significantly associated with total cerebral tissue, WM, and subcortical brain tissue volume reductions (Table 2; $b = -0.01 \text{ cm}^3/\text{y}$), and with parietal WM, lateral ventricles, and sulcal CSF volume enlargements ($≥0.18 \text{ cm}^3/\text{y}$).

Because they may be confounders, we adjusted our analysis of treatment effects by statistically correcting for the effects of follow-up duration, illness severity, and substance misuse. Antipsychotic treatment still had significant main effects on total cerebral and lobar GM and putamen volumes (Table 2; $F ≥ 4.33, P ≤ .04$). Higher antipsychotic dose was associated with smaller GM volumes ($b = -0.03$) and larger putamen ($b = 0.01$). Antipsychotic treatment effects on GM volumes were independent of follow-up duration (Table 2; antipsychotic treatment × follow-up duration interaction term $F ≤ 1.17, P ≥ .28$). On the other hand, there were statistically significant treatment × time interaction effects on total cerebral tissue volumes, total cerebral and lobar WM, lateral ventricles, and sulcal CSF, caudate, putamen, and cerebellar volumes (Table 2; $F = 3.79, P ≤ .05$). Higher doses of antipsychotic treatment were associated with greater reductions in WM, caudate, and cerebellar volumes over time ($b = -0.0003$), and with greater CSF volume and putamen enlargements ($b = 0.0008$).

To further illustrate how brain volume trajectories may differ according to the amount of antipsychotic treatment, patients were grouped into tertiles of mean daily antipsychotic dose: most treatment (70 patients; mean dose, 929.4 CPZ mg equivalents/d), intermediate treatment (70 patients; mean dose, 391.7 CPZ mg equivalents/d), and least treatment (71 patients; mean dose, 111.5 CPZ mg equivalents/d). The Figure shows individual subject brain volume trajectories and treatment tertile group mean brain volume trajectories for total cerebral WM, lateral ventricles, and frontal GM volumes. We then conducted an extreme group comparison to contrast brain volume changes between the most and least treatment groups. Random regression coefficient mixed model analyses were duplicated replacing antipsychotic dose with tertile group membership (most vs least treatment) and included a tertile group × follow-up duration interaction term.

For total cerebral WM and lateral ventricles, there were statistically significant main effects of tertile group × time interaction (Figure, A and B; $t ≥ 2.28, P ≤ .02$), indicating that brain volume trajectories differed significantly across tertile groups of antipsychotic treatment. The least-treatment group showed increased total cerebral WM over time in contrast to WM volume reductions among patients in the most-treatment group (mean regression slopes, 1.30 vs −0.64, respectively). Similarly, patients in the most-treatment group had greater enlargement of lateral ventricles than those in the least-treatment group (Figure, B; mean regression slopes, 0.39 and 0.16, respectively). Consistent with the previous random coefficient regression mixed-model analyses where antipsychotic treatment was entered as a continuous measure, extreme tertile group contrast found significant main effects of tertile grouping on frontal GM volumes ($t = 2.19, P = .03$). Patients who received the most antipsychotic treatment had smaller frontal GM volumes, and this difference was independent of follow-up duration (group × time interaction, $t = 1.32, P = .18$).

Patients who received the most antipsychotic treatment had smaller baseline total cerebral tissue and larger lateral ventricles than the other 2 tertile subgroups.
Figure. Comparison of magnetic resonance imaging brain volume trajectories between tertiles of antipsychotic treatment. Tertiles were categorized as those who received the most treatment (70 patients; mean [SD] dose, 929.4 [47.7] chlorpromazine [CPZ] mg equivalents/d), intermediate treatment (70 patients; mean [SD] dose, 391.7 [77.2] CPZ mg equivalents/d), and the least treatment (71 patients; mean [SD] dose, 111.5 [87.7] CPZ mg equivalents/d). Individual patient brain volume trajectories (thin lines) and treatment tertile group mean brain volume trajectories (thick lines) are shown for total cerebral white matter (A), lateral ventricles (B), and frontal gray matter volumes (C).
(F ≥ 5.30, P ≤ .006). There were no statistically significant differences between the treatment tertile groups regarding the other baseline brain volumes (F ≤ 2.95, P = .06).

INDEPENDENT EFFECTS OF ILLNESS SEVERITY AND SUBSTANCE ABUSE ON BRAIN VOLUMES

After controlling for the other 3 predictors, mean GAS score had significant main effects on total cerebral GM and frontal GM volumes (Table 2) (F ≥ 4.38, P ≤ .04). Less illness severity was associated with increased brain tissue volume (b = 0.27). There were no statistically significant main effects of mean GAS score on the other brain volumes (F ≤ 3.65, P ≥ .06).

The majority of the sample (68.3%) did not meet criteria for alcohol abuse/dependence or illicit drug abuse/dependence. Seven patients had alcohol abuse/dependence only, 13 marijuana abuse/dependence only, 8 alcohol and marijuana abuse/dependence only, 19 alcohol abuse/dependence and nonmarijuana illicit drug abuse/dependence, and 30 nonmarijuana illicit drug abuse/dependence only. Severity of alcohol/illicit substance misuse had no significant main effects on brain volumes (Table 2) (F ≤ 1.69, P ≥ .20) except on lateral ventricles (F = 5.60, P = .02; b = 2.44) and on cerebellar volumes (F = 5.48, P = .02; b = −3.25).

INDEPENDENT EFFECTS OF ANTIPSYCHOTIC CLASS ON BRAIN VOLUMES

To explore whether typical antipsychotics, nonclozapine atypical antipsychotics, and clozapine may have differential effects on brain volumes in schizophrenia, we repeated the mixed-models analyses in Table 2 by replacing mean daily (total) antipsychotic dose with lifetime mean daily doses of typical antipsychotics, nonclozapine atypical antipsychotics, and clozapine up until the time of each MRI scan (covariates: initial intracranial volume, sex, imaging protocol, and age at initial scan; other fixed effects: follow-up duration, mean GAS score, and substance misuse severity; and random effects: follow-up duration and intercept term).

There were significant main effects of typical antipsychotic dose, nonclozapine atypical antipsychotic dose, and clozapine dose on GM brain volumes (Table 3). Higher typical antipsychotic doses were associated with smaller total cerebral GM and frontal GM volumes (F ≥ 4.82, P ≤ .03). Higher doses of nonclozapine atypical antipsychotics were associated with lower frontal and parietal GM volumes (F ≥ 0.74, P = .01), and higher clozapine doses were associated with smaller total cerebral and lobar GM volumes (F ≥ 10.90, P ≤ .001). For WM volumes, higher nonclozapine atypical antipsychotic doses were significantly associated with larger parietal WM volumes (F = 4.34, P = .04). There were no statistically significant main effects of typical antipsychotic class or nonclozapine atypical antipsychotic class on the remaining WM brain volume measures or on lateral ventricles. Higher clozapine doses were associated with larger sulcal CSF volumes and smaller caudate, putamen, and thalamic volumes (F ≥ 4.70, P ≤ .03). Enlarged putamen was associated with higher doses of both typical and nonclozapine atypical antipsychotics. Treatment with higher doses of nonclozapine atypical antipsychotics was also associated with caudate volume enlargement.
In this large longitudinal cohort of patients with schizophrenia (211 patients with 674 MRI scans) who were in their first episode and had received minimal treatment at the time of entry into the study, we examined the independent effects of 4 variables on progressive brain volume change during an extended period: illness duration, antipsychotic treatment, illness severity, and substance misuse. We found that longer follow-up was associated with a greater decrease in brain tissue volumes. Antipsychotic treatment also had a significant influence on brain volumes even after accounting for the potential confounds of the other 3 variables. More antipsychotic treatment was associated both with generalized tissue volume reduction involving multiple subregions and with a specific increase in putamen. The other 2 variables, severity of illness and substance abuse, had minimal or no effects. Progressive brain volume changes during the lifelong course of schizophrenia, including GM and WM volume reductions, CSF volume expansions, and basal ganglia volume enlargements, appeared in part to be related to antipsychotics. These findings may potentially have clinical implications for the use of long-term antipsychotic treatment.

The plausibility of long-term antipsychotic treatment leading to global brain volume reductions is further supported by recent controlled studies in macaque monkeys.10-21 Animal studies provide an additional perspective on possible causative links because they permit postmortem neuropathological examination of the brain. Dorph-Petersen et al administered haloperidol, olanzapine, or sham medication to macaque monkeys in doses that produced plasma levels equivalent to those observed in treatment of schizophrenia patients. After 17 to 27 months of treatment, both haloperidol- and olanzapine-treated monkeys had an equivalent and highly significant 8% to 11% decrease in fresh brain weight and volume when compared with the sham group. These decreases affected all major brain regions but were most robust in frontal and parietal lobes. The neuropathological manifestations of antipsychotic-related frontoparietal volume reductions in macaque monkeys involves decreased astrocyte numbers, decreased dendritic arborization, decreased dendritic spine density, and increased neuronal density with no neuronal loss.20,21 Although there have been some conflicting findings in the nonhuman primate literature (eg, studies by Lidow et al and Sweet et al), these neuropathological changes are strikingly similar to those described in the schizophrenia postmortem literature (eg, studies by Pakenberg and Seelen et al).

These findings are also consistent with previous MRI studies suggesting that antipsychotics produce changes in the human brain that are measurable by in vivo neuroimaging techniques. The earliest work with morphometric MRI found increased basal ganglia size in schizophrenia patients, typically in the putamen.45-46 Subsequent studies have shown that this may be a medication effect and that typical antipsychotics in particular play a causal role in basal ganglia enlargement.47-51 Positron emission tomography studies measure cerebral blood flow and, by inference, cellular metabolism. Previous positron emission tomography studies conducted by our group52-54 confirm that both typical and atypical antipsychotics increase putamen cerebral blood flow. In addition, antipsychotics reduce frontal cerebral blood flow, suggesting that chronic frontal hypoperfusion could be a mechanism underlying smaller brain tissue volumes. However, the available studies that have used morphometric MRI to examine the effects of antipsychotics on cortical GM have yielded ambiguous results,55-57 possibly due to small sample sizes, differing duration of treatment assessment, variation in brain regions measured, and discrepant measurement techniques.

In the present study, WM but not GM volumes showed significant time × antipsychotic treatment interaction effects. Although higher antipsychotic doses were associated with a decrease in GM volumes, this relationship did not appear to change during the course of longitudinal follow-up in our study. A change in WM volume trajectories, on the other hand, was associated with antipsychotic treatment. As illustrated by the extreme tertile treatment group comparisons, patients in the most-treatment group had longitudinal WM volume reductions. As a group, patients with the least treatment showed WM volume increases over time that would be expected of individuals during their third and fourth decades of life.50 Bartozkis and colleagues previously found that patients with schizophrenia do not show the normal age-related WM volume expansion during early to mid-adulthood. Thus, the treatment × time interaction effects in the present study suggest that WM volume deficits in schizophrenia may, in part, be related to antipsychotic treatment. Our study found that all 3 classes of antipsychotics (ie, typical, nonclozapine atypical, and clozapine) were associated with deceases in GM brain volumes. The only differential effects on brain volumes between typical and nonclozapine atypical antipsychotics were in parietal WM and caudate measures. These typical-atypical differential effects on brain volumes in our study differ somewhat from a recent randomized treatment study.10 Lieberman and colleagues found that haloperidol treatment was associated with progressive GM volume reductions during that 2-year study. In contrast, olanzapine-treated patients did not show GM volume decrement. This raises concerns regarding the possibility of typical antipsychotic-associated neurotoxic effects. Our study suggests that atypical antipsychotic treatment may mitigate parietal WM volume loss in patients with schizophrenia; this finding needs to be interpreted with caution and will require support from additional well-designed clinical trials in first-episode patients.

Our results must be interpreted in the context of additional limitations. Identifying an association does not necessarily indicate a causal relationship. Furthermore, observational studies involving long durations such as ours inevitably preclude use of the “gold standard”: a random-assignment controlled trial. The current study could have been strengthened by having control groups, eg, schizophrenia patients assigned to deferred or no antipsychotic treatment or healthy volunteers treated with antipsychotics for comparable periods. However, ethical standards in human subject research prohibit such
The small number of schizophrenic patients in our sample who received no antipsychotic treatment did not allow for meaningful statistical analyses. Illness severity and antipsychotic dosages were modestly correlated (Spearman $r = -0.21$), and patients who received the most treatment had smaller baseline cerebral tissue volumes. Associations between smaller brain tissue volumes and more antipsychotic treatment may still be moderated via illness severity despite our inclusion of illness severity as a covariate and obtaining similar results from different measures of illness severity. Even with the most sophisticated statistical methods, we may not be able to fully distinguish the potential confounding influences that illness severity or other sources of unmeasured variance could still have on the relationships between progressive brain volume reductions and antipsychotic treatment. Last, although our Talairach atlas-based lobar measures have well-established reliability and validity, these cerebral brain volumes lack precision to delineate abnormalities within smaller subregions implicated in schizophrenia (eg, superior temporal gyrus and prefrontal cortex).

Findings from the present study raise several clinical questions. Are antipsychotic-associated GM and WM volume reductions “bad” for patients? The implicit assumption is that brain volume reductions are probably undesirable because patients with schizophrenia already have diffuse brain volume deficits at the time of illness onset. Schizophrenia patients with poor outcomes are also more likely to have smaller brain volumes. However, the neurobiological changes that underlie MRI measurements of antipsychotic-associated brain volume decrement remain poorly understood. Some studies indicate that antipsychotic-induced changes mimic the neuropathological changes of schizophrenia,$^{20,21}$ while others suggest otherwise.$^{41,42}$ If antipsychotics do indeed result in deleterious brain tissue volume reductions, how does this influence the risk-benefit ratio of antipsychotic treatment? Given that these medications have substantially improved the long-term prognosis of schizophrenia and that schizophrenia is a disease with significant morbidity, continued use of antipsychotics is clearly still necessary. However, our findings point toward the importance of prescribing the lowest doses necessary to control symptoms. They also imply the need for rethinking the target at which treatment is aimed, and the possibility that antipsychotic treatment may improve psychotic symptoms but also contribute to progressive brain tissue volume deficits. Antipsychotics were designed for the purpose indicated by their name, ie, to arrest psychosis. Not only is it probable that antipsychotics do not treat the fundamental pathophysiologic mechanism of schizophrenia (ie, the brain disease), but we perhaps must also entertain the possibility that they might have potentially undesirable effects of brain tissue volume reductions. In conjunction with neuroscientists and clinical investigators, pharmaceutical companies must continue the vigorous search for agents that are genuinely neuroprotective.

The second-generation antipsychotics are also now widely used for people who do not have schizophrenia, including children, the elderly, and patients with bipolar disorder or depressive disorders.$^{27-30}$ They are also used in adolescents who have been identified to be at high risk for schizophrenia. Our findings may lead to heightened concerns regarding potential brain volume changes associated with the sharp rise in atypical antipsychotic use in non-schizophrenia psychiatric disorders. Even though some studies have assessed the long-term effects of antipsychotics on brain volumes in non schizophrenia patients, our results suggest that antipsychotics should still be used with caution in these patient groups after careful risk-benefit assessment. Because typical antipsychotics are off patent and less expensive than atypical ones, there is also a growing trend to prescribe them preferentially for patients with schizophrenia. Given that these older medications carry a greater risk of producing extrapyramidal adverse effects and tardive dyskinesia, such a shift in clinical practice may produce deleterious effects on the primary diseased organ in schizophrenia: the brain.

**CONCLUSIONS**

Antipsychotics are effective medications for reducing some of the target clinical symptoms of schizophrenia: psychotic symptoms. In medicine we are aware of many instances in which improving target symptoms worsens other symptoms. Hormone therapy relieves menopausal symptoms but increases stroke risk. Nonsteroidal anti-inflammatory drugs relieve pain but increase the likelihood of duodenal ulcers and gastrointestinal tract bleeding. It is possible that, although antipsychotics relieve psychosis and its attendant suffering, these drugs may not arrest the pathophysiologic processes underlying schizophrenia and may even aggravate progressive brain tissue volume reductions.

Submitted for Publication: March 5, 2010; final revision received September 14, 2010; accepted September 15, 2010.

Correspondence: Beng-Choon Ho, MRCPsych, Department of Psychiatry, W278 GH, University of Iowa Carver College of Medicine, 200 Hawkins Dr, Iowa City, IA 52242.

Author Contributions: Drs Ho and Andreasen had full access to all the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis.

Financial Disclosure: Dr Ho receives grant support from Ortho-McNeil Janssen Scientific Affairs. Dr Andreasen has served on the Ortho-McNeil Janssen Advisory Board and receives grant support from Ortho-McNeil Janssen Scientific Affairs.

Funding/Support: This research was supported in part by grants MH68380, MH31593, MH40856, and MH3271 from the National Institute of Mental Health.

Role of the Sponsor: The National Institute of Mental Health financially supported the design and conduct of the study; the collection, management, analysis, and interpretation of the data; and the preparation of the manuscript, but was not involved in manuscript review or approval.
Online-Only Material: The supplementary Methods and References and the eFigure and eTables are available at http://www.archgenpsychiatry.com.

Additional Contributions: Dawei Liu, PhD, provided valuable advice and assistance in statistical analysis.
